Doonan, I.J.; Dunn, M.R. (2011). Trawl survey of Mid-East Coast orange roughy, March-April 2010. New Zealand Fisheries Assessment Report 2011/20.

This series continues the informal New Zealand Fisheries Assessment Research Document series which ceased at the end of 1999.

#### **EXECUTIVE SUMMARY**

# Doonan, I.J.; Dunn, M.R. (2011). Trawl survey of Mid-East Coast orange roughy, March-April 2010.

#### New Zealand Fisheries Assessment Report 2011/20.

A trawl survey of the Mid-East Coast (MEC) orange roughy management area was conducted using NIWA's 70 m fisheries research vessel *Tangaroa* in March-April 2010. The survey was a repeat of the 1992–94 surveys over the same area and used a similar design. The 2010 survey used the same vessel, trawl net, trawl warp lengths, and fishing protocols. The survey used a two phase design, with phase 1 stations selected from those that had already been used in one or more of the 1992–94 surveys. The 1992–94 surveys were re-analysed to ensure the time series (1992–94 and 2010) was comparable, and suitable for use in a stock assessment.

In 2010, a total of 187 trawl tows were completed in 33 strata, of which 142 were successful phase 1 stations, 29 were successful phase 2 stations, and 16 were rejected because of poor gear performance. A total catch of 107 t was recorded from all trawl stations. During the voyage 275 species or species groups were recorded. Gonad samples, stomachs, and otoliths were taken from orange roughy. Otoliths or dorsal fin spines were removed from 10 other bycatch species. A total of 14.31 km of fish were measured for length, consisting of 32 713 individual fish.

Two alternative methods were used to estimate abundance. Using the all-relevant-tows method, the total abundance of orange roughy was estimated to be 6800 t (c.v. 17%), which was lower than the average over the 1992–94 surveys, which was 15 300 t (15%). The greatest reduction in abundance was for pre-recruit orange roughy, i.e., from 8900 t to 3300 t. Similarly, using the first-at-site method for the 1992–94 surveys and for 2010, reducing the allocation of phase 2 tows to 10%, the total abundance of orange roughy was estimated to be 7100 t (c.v. 19%), lower than the average of the 1992–94 surveys of 16 200 t (16%). Again, the greatest reduction in abundance was for pre-recruit orange roughy, i.e., from 10 400 t to 3400 t.

Although efforts were made to ensure the 2010 survey was comparable to the 1992–94 surveys, the 2010 survey had a lower trawl net headline height, a slightly smaller door spread, a slightly larger wingtip distance, and a greater between tow distance. However, the surveys used the same vessel, net, towing practice, survey design, and even some officers; and the warp-to-depth ratios, expected phase 2 bias, total bycatch abundances, and orange roughy vulnerability (at size), were all similar. Overall, there was little evidence that the trawl net was less efficient for orange roughy in 2010, and the differences in net parameters seemed unlikely to explain the extent of the observed decrease in the biomass estimates for orange roughy.

#### **1. INTRODUCTION**

The Mid-East Coast (MEC) orange roughy stock has supported one of the largest and most persistent orange roughy fisheries around New Zealand. The landings peaked at 10 500 t in 1989–90 and were maintained for several years at this level before catch limits were reduced in the mid 1990s. The "fishing down" phase for this orange roughy stock was completed by the mid 1990s, by which time the cumulative reported landings exceeded 100 000 t (Dunn 2005).

A variety of fishery independent methods for estimating MEC orange roughy biomass have been used for stock assessment, including egg surveys and acoustic surveys to estimate absolute biomass, and trawl surveys to measure relative biomass (Clark 1996, Dunn 2005). Fishery dependent methods, specifically standardised catch per unit effort (CPUE) have been used for the MEC (Dunn 2005; Anderson & Dunn 2008), but are less desirable because they are particularly susceptible to bias (e.g., Clark et al. 2010).

The recent distribution of spawning orange roughy on the MEC, in particular a relatively small school size with a less predictable distribution, has made the acoustic biomass estimation technique problematic, and potentially subject to large biases (Doonan et al. 2004). Spawning biomass estimates from egg production surveys have not been repeated, as the large spawning aggregations which this method would seek to measure are no longer present. Amongst the fishery-independent stock monitoring methods, this leaves the trawl survey as the only viable option. It was found that repeating the survey method used in the 1992–94 RV *Tangaroa* surveys in 2010 could have substantial leverage in future stock assessments (Dunn 2009). As a result, in March-April 2010, a repeat trawl survey of the MEC was conducted using RV *Tangaroa*.

A primary concern for the 2010 survey was to ensure that it was sufficiently comparable with the 1992–94 surveys that the series could be used for stock assessment. To this end, the same vessel, trawl gear and operation and survey design were used in 2010 as in the 1992–94 surveys. However, the earlier surveys required some adjustments to make them consistent with the 2010 survey. This included excluding the most northern area of the 1992–94 surveys (the region of ORH 2A outside the MEC stock area, known as East Cape (EC), which was defined in 1994–95), using a consistent wingtip distance for biomass estimates, and reallocating some tows into consistent strata.

The work described in this report was carried out under Ministry of Fisheries project ORH2007/01, having the overall objective "To estimate the abundance of orange roughy (Hoplostethus atlanticus) in selected areas.", and the specific objective "to estimate the abundance of orange roughy for the Mid East Coast (MEC) stock, from a trawl survey with a target coefficient of variation (c.v.) of the estimate of 20-30 %."

#### 1.1 Review of previous trawl surveys

The first survey series of the MEC stock took place during 1985–87, at spawning time (June-July), and this was followed by a survey in September-October 1988 (Robertson & Grimes 1987, Fincham et al. 1987, Banks & Annala 1989). These surveys covered only part of the MEC stock distribution.

The precursor to the 1992–94 surveys took place during 1989 and 1990, and these surveys covered the whole of the MEC and EC (quota management areas ORH 2A, 2B, and 3A), depths from 600 m to 1500 m, and were conducted in September-October (Grimes 1990, 1991). The 1989–90 surveys established the survey area, strata and design used for the 1992–94 surveys (Figure 1), and also provided most of the tow positions that were re-used in the latter surveys. The design was stratified random, with two phases (Francis 1984), with a minimum of three stations allocated to each stratum. The vessels used were FV *Will Watch* and RV *Cordella*.

The *Tangaroa* survey series began in 1992, during March-April to avoid possible future clashes in vessel programming (Grimes 1994). The 1992 survey covered the same area as the 1989 and 1990 surveys, but included three new strata based on areas of high commercial catch and catch rates (over 5 t/tow) achieved during March 1990 and 1991. The three new strata covered a relatively small area, and therefore to allow a sufficient number of tows to be completed within them they were not stratified by depth. Except for the new strata, the 1992 survey repeated research trawl positions from the 1990 survey, but without maintaining the same tow direction.

The 1993 survey was similar to that in1992, with some minor modifications to strata. The East Cape and Tolaga sub-areas were combined into a single sub-area, resulting in four less strata, and two further strata were added based upon commercial catches. There was also a redistribution of tows amongst strata based on the 1992 survey results, and an increase in the overall number of tows (Tables 1 & 2). Except for the two new strata, the previous known tow positions were again used. The survey design was unchanged in 1994.

For the 1992–94 surveys, a standard tow length of 2.0 nautical miles at a towing speed of 3.0 knots over the ground was used. The distance towed was determined using Global Positioning System (GPS). During the surveys, some tows were shortened because the ground was too rough to complete the tow path. In a few cases, the trawl gear was flown above the bottom for a short period if it looked possible to get it down again within 20 minutes, and therefore extend the tow length to achieve the required 2.0 nautical miles. In the few instances where the trawl was flown (Table 3), the distance towed was recorded as the sum of the distances during which the net was in contact with the bottom.

The warp to depth ratio generally ranged from 1.7 to 2.1. The procedure used was to start the tow with an expected ratio of 1.7, and let out more warp as required. The tows on hills and deep tows tended to have a lower ratio, close to 1.8, to maintain better control of the net, and the shallower tows tended to have a ratio closer to 2.0. The net used in 2010 was the same as used in 1992–94, and was similar to that used during the 1989 and 1990 surveys. The net is commonly referred to as the "rough bottom roughy net", and it is an Alfredo-style trawl designed for use on rough ground, with large rollers fitted to the ground rope, cut-away lower wings, and a wingspread of about 25 m (Appendix 1).

To estimate orange roughy abundance, a constant door spread of 115 m was assumed for the 1992 survey, and 110 m for 1993–94, based upon door spread sensor readings (Grimes 1994, 1996a, 1996b). It was assumed that there was no herding of orange roughy by the trawl doors and sweeps, with vulnerability calculated to be 0.243 in 1992 and 0.227 in 1993 & 1994, given a trawl wingtip distance of 28 m in 1992 and 25 m in 1993–94 (I do not understand how you can know the vulnerability, do you mean the difference between door spread and wing spread? We do not; this is the term used by Grimes and the parameter name used in the biomass program he used) (Grimes 1994, 1996a, 1996b). Vertical and areal availability were assumed to be 1.0 (Grimes 1994, 1996a, 1996b). The reported total abundances by sub-area are shown in Table 4.

#### 1.2 Survey design

The 1992–94 MEC surveys used a two-phase design, which introduces a modest negative bias, but protects the survey from extreme high estimates (Francis 1984). The proportion of phase 2 tows in the overall survey was 26% in 1992, 23% in 1993, and 21% in 1994. These are in line with the Francis (1984) recommendation of 25% for a new survey, but Francis (2006) recommends that only about 10% are needed if the design is based on past surveys.

Phase 2 tows appear to be needed for the MEC survey because the strata with the greatest estimated biomass have not been predictable (except for perhaps stratum 33). Later in this document, we complete simulations using data from the 1993 and 1994 surveys to investigate the likely size of the bias in biomass estimates resulting from the two phase design.

In the 1992 survey, phase 2 stations appeared to have been poorly applied, since 26 phase 2 stations (out of 51) were allocated to stratum 45, which only had 4 phase 1 stations, and this stratum contributed just 144 t (1%) to the total biomass. However, part of this stratum was split off into a commercial stratum after the phase 2 stations were completed, and the tows in the new commercial stratum were then repeated.

The design of the 1992–94 surveys was not a true stratified random design, but had fixed position phase 1 stations, and stratified random phase 2 stations allocation each year. The use of fixed stations during phase 1 reduced search time and gear damage. The MEC contains many rough ground areas, and the time required to complete a true stratified random phase 1 survey would have proven prohibitive. For the 1992–94 surveys, there was a core of 110 phase 1 stations, with some new phase 1 stations added, and others used only once (Table 5). Since stations could be fished in any direction, for example in response to swell direction, a repeated tow can be considered analogous to a site covering a disc of 1 to 2 nautical miles in diameter, rather than being a single tow path. There were at least 158 of these potential tow sites to choose from for phase 1 of the 2010 survey (Table 5).

A true fixed station design has a bias, but this is compensated for by a lower variance than a random design (random designs being unbiased). The extent of the bias in a fixed station design depends on the strength of any residual trends in density within a stratum (i.e., spatial and temporal correlations). If the bias is constant, then it becomes part of the survey catchability. However, adding more stations and re-distributing the numbers of stations between strata, as was done in 1993 and 1994 surveys, changes the size of the bias. If spatial correlation is weak then the bias is small and it becomes like a random design. Fixed stations surveys are considerably faster to complete (estimated to be about 40% faster for the MEC survey) because trawl tracks do not have to be surveyed first and if unsuitable, another site found nearby.

When fixed station positions from the 1992–94 survey data were examined, it appeared that some were repeated twice or more during the same survey. This could be just a consequence of the spatial scale at which we examined position data, or it could be due to the limited number of suitable tow positions in a stratum, especially when the phase 2 tows tended to be allocated to one or two strata in high densities relative to the stratum area.

The order of occupation of strata was different for all three surveys (Table 6). This was primarily because of weather conditions, which often vary throughout the survey area, with Wairarapa being especially prone to periods of relatively high winds.

## 2. METHODS

### 2.1 Orange roughy abundance estimation

#### 2.1.1 Sites

For the 2010 survey, we planned to repeat stations fished during the 1992–94 surveys. As outlined above, actual tows tracks differed at the same (nominal) tow position, because different weather in each year required a different tow direction. A preliminary analysis found that many of the 1992–94 tow positions were clustered into sites approximately 2 nautical miles across, and that there was some evidence for spatial correlation of catch rates within sites. As a result, the potential tows were clustered into sites, and each of these sites was repeated in the 2010 survey. For the 2010 survey, one tow from each site was randomly selected as the tow line for the 2010 survey.

The list of phase 1 and known phase 2 sites were generated from a hierarchical cluster analysis based on squared Euclidean distance between tow mid-point locations. All tow locations from the 1992–94 surveys were used. The analysis was done using the *hclust* function in R (Murtagh 1985, R Development Core Team 2009) with the agglomeration method set to *average*. Sites were extracted from the resulting hierarchical tree using a *height* of 2.25 nautical miles. This tree height is slightly larger than the normal tow length of 2 nautical miles, so that end-on-end tows were selected as being in the same site. In a few cases, overlapping clusters were merged by hand (two clusters into one for strata 3, 31, 33; 3 clusters into one for stratum 13), and one cluster was split into two (stratum 4). Some examples of sites and their constituent tow lines, including two clusters merged into one site, are shown in Figure 2. Phase 1 sites were defined as those sites containing at least one tow in phase 1, for at least one of the 1992–94 surveys. The strata based on commercial hill fishing, strata 1 to 5, were done differently in each of the 1992–94 surveys, so three sites within each strata were designated as phase 1 sites by hand, for the 2010 survey.

The exception were the commercial strata (1 to 5), where 3 phase 1 sites were designated by hand and the others assigned as phase 2 sites since it was difficult to work out what was a phase 1 or II tow, i.e., in some years, some commercial strata had all tows designated as phase 2.

The number of sites identified for phase 1 was 144, and for phase 2 was 68. The tows assigned to each site for phase 1 and II are given in Appendix 2. The notion of a site, as defined here, meant that the 1992–94 surveys repeated some sites, mainly during phase 2 (Table 7).

### 2.1.2 Survey design

The 2010 survey repeated the design from the 1993-94 surveys (Figures 1 & 3, Tables 1 & 2), except that the EC sub-area was truncated at latitude 38° 23' S, in accordance with the management boundary between the EC and MEC stocks that was in place since 1994–95.

The survey had a stratified design using 144 fixed phase 1 sites and a target of 20% phase 2 sites. Phase 2 tows were allocated to strata following Francis (1984), and selected from the list of additional known sites for each stratum. Where there were not enough sites, new potential sites were randomly generated within the target stratum. Each new site had to be at least two nautical miles from existing sites.

#### 2.1.3 Data analysis

Abundance estimates using wingtip swept area were made for all orange roughy, juvenile (<32 cm standard length (SL)), and adults ( $\geq$  32 cm SL) orange roughy, and also for main bycatch species. All abundance estimates, and stratum allocation of phase 2 tows, were made using the NIWA software *SurvCalc* (Francis & Fu 2009). *Survcalc* is a C++ computer program developed in 2008 to analyse data from stratified random surveys.

The trawl catch of adult orange roughy in the  $i^{th}$  trawl in stratum *s* was converted into fish weight density  $(d_{si})$  using a fixed wingtip width of 25 m. A catchability (q) of 1 was assumed. Thus, the biomass will be given by:

$$\sum_{s}^{strata} A_s \overline{d}_s$$

where  $A_s$  is the stratum area of stratum s, and  $\overline{d}_s$  is the mean density in stratum s.

The variance is given by:

$$\sum_{s}^{strata} A_{s}^{2} \frac{V_{s}}{n_{s}}$$

where  $V_s$  is the sample variance estimate of densities and  $n_s$  is the number of tows in stratum s.

Orange roughy scaled length frequencies distributions by stratum and overall were calculated using *SurvCalc* from the length and weight samples collected during the survey.

The stratum areas for 2010 were the same as used in the 1993–94 surveys. For the abundance estimates for the 1992–94 surveys, the stratum areas used are those reported by Grimes (1994, 1996a, 1996b).

#### 2.2 Survey execution

The survey work was carried out using NIWA's 70 m research vessel *Tangaroa*. All tows used a rough-bottom orange roughy trawl, having the same design as used in the 1992–94 surveys (Appendix 1). This an Alfredo-style trawl, with cut-away lower wings, 305 mm (12 inch) mesh in the forepart of the net reducing to 102 mm (4 inch) mesh, with a 100 mm mesh cod-end, robust ground gear consisting of steel and rubber bobbins, and an expected wingspread of about 26 m and headline height of about 6 m.

Trawl survey work was carried out 24 hours a day. Each trawl tow lasted for 2 nautical miles at 3 knots, whenever possible. The door-spread and headline height, and wing-tip width where possible, were recorded at five minute intervals during each tow from SCANMAR readings. Warp to depth ratios were the same as previously used at each site, and close to 2.0 except on hills, where they were roughly 1.8. To check that the net consistently conformed to the 1994 net plan, the trawl was regularly measured, and any components (e.g., sweeps or bridles) replaced if necessary (e.g., if there was any evidence of stretching after the trawl came fast). Prior to the survey, the net was shipped to Motueka Nets to confirm that it conformed to the net plan.

Any tows that were not successful on the first attempt were not repeated immediately, and the site was rested for at least 24 hours.

The catches from each valid tow were sorted and weighed by species on motion compensating scales to the nearest 0.1 kg. Large catches of fish were sub-sampled and the total catch estimated from the proportions in the sample. For catches too large to be weighed, the catch was estimated from the weighed processed catch using a conversion factor. From each tow, a random sample of up to 200 orange roughy, and 50–200 of other species were randomly selected from the catch to be measured and sexed. Up to 40 individuals of orange roughy were selected randomly for more detailed biological analysis, which included fish length, weight, sex, gonad stage and weight, and otolith extraction.

#### 2.3 Survey recalculations for 1992–94

Two alternative estimates were completed. The first used the survey data as originally collected but with some minor changes ("all-relevant-tows"), and second used only the first trawl at each of the specified sites ("first-at-site").

Some tows in the original calculations were assigned to the wrong strata. These were tows within the new commercial strata, that had been assigned to the parent stratum (since they were done before the new commercial stratum was split off), which had not been corrected after the survey was completed (Table 8).

There was only one trawl in each of the new strata (truncated at latitude  $38^{\circ} 23^{\circ} S$ ) for the Tolaga sub-area in the 1993 and 1994 surveys, so only one station per stratum was available. In these cases, the single station was used as an estimate of abundance, with the coefficient of variation (c.v.) set to 95%. To implement this in *SurvCalc*, another tow was artificially generated and the catches of both tows in the stratum changed so the mean remained the same as the actual catch from the single tow, but the c.v. was 95%.

For the all-relevant-tows estimates, all tows with good performance were used.

For the first-at-site estimates, each phase 1 tow was from a different site. For the first-at-site estimates, the first tow at each site was used for phase 1 sites and phase 2 sites. Phase 2 tows on phase 1 sites were excluded which resulted in substantially fewer phase 2 tows than in the original surveys. Fewer phase 2 tows reduces the phase 2 bias so to make the 2010 survey comparable, the number of phase 2 tows were reduced in 2010 so that the phase 2 bias was similar to the first-at-site estimate for 1992–94 number of phase 2 tows is 10% of phase 1 tows).

All survey estimates were calculated assuming a constant wingtip width of 25 m.

#### 2.4 Comparability across surveys

A key activity for this project was to assess comparability across the four surveys. Comparability can be thought of as having two components; catchability (variability caused by survey conditions, fish life history, environment etc) and bias (caused by, for example, using a phase 2 design). To help evaluate comparability, trawl operation and net parameter distributions were

compiled, the abundance of by-catch species was estimated, and the bias from using phase 2 tows estimated.

Wingtip distance, doorspread distance, headline height, and warp length distributions were compiled for all surveys, and relationships investigated with each other, and also with depth and tow direction (up or down the slope).

Bycatch abundance was estimated for all of the regularly caught species, using the all-relevanttows method, for the 1992–94 and 2010 surveys. The objective of this analysis was to see if there was an overall change in catch rate that would suggest a change in catchability or net efficiency.

#### 2.5 Expected bias from using phase 2 stations

The estimation of the expected bias from using a two-phase design followed Francis (1984), using data from the 1993 and 1994 MEC surveys. The catch data were for recruited fish  $(\geq 32 \text{ cm SL})$ . We assumed a completely random design. In preliminary investigations, the method was extended to fixed sites that had between year correlations at a site, but the overall expected bias was found to be similar to that estimated when using a completely random design. The method assumed that all abundances were lognormal with a common variance in log space. The East Cape stratum areas were adjusted to the Tolaga strata area for 2010. For 1993, stratum 5 was excluded, since it was not included in phase 1 of the 1993 survey. Thus, there were 160 phase 1 tows in 1993, and 166 phase 1 tows in 1994. Simulations of the phase 2 allocation based on results of phase 1 were carried out using 2000 simulations on each survey. The c.v. and bias were averaged over the two surveys. Simulations were carried out with phase 2 allocation at 5%, 10%, 15%, 20% or 25% of the number of phase 1 tows. For re-calculated abundances for 1993 and 1994 (Section 2.3), slightly lower numbers of phase 1 tows were used; for the first-at-a-site method there were 156 phase 1 tows for 1993 and 160 phase 1 tows in 1994. These were considered close enough to the initial estimates (160 and 166 phase 1 tows respectively) that extra calculations were not warranted.

#### 3. RESULTS

#### 3.1 Survey execution

A total of 187 trawl tows were completed in 33 strata, of which 142 were successful phase 1 stations, 29 were successful phase 2 stations, and 16 were rejected because of poor gear performance. Tow positions for valid tows are shown in Figure 4. There were two phase 1 stations not successfully completed, otherwise all planned tows were completed (Table 9). Tow details are given in Appendix 3. A total catch of 107 t was recorded from all trawl stations (Table 10).

Weather conditions were good throughout the voyage, and no time was lost due to unfavorable sea conditions (Appendix 4). The RV *Tangaroa* trawl survey overlapped with a Crown Minerals seismic survey off the Wairarapa coast. This survey consisted of two vessels, MV *Reflect Resolution* and *Ocean Pioneer*, with *Reflect Resolution* using a loud acoustic "boomer", and multiple listening devices fixed on the seabed. The equipment on the seabed was not located near any *Tangaroa* survey sites. Nevertheless, because of concerns about the acoustic "booming" potentially influencing fish catchability, *Tangaroa* moved position to start work about 60 n. miles

(110 km) north of the seismic survey area, only returning to start the Wairarapa strata roughly 2 days after the seismic survey (their final transect, 100 km offshore) had been completed.

Commercial surface longlines initially prevented access to stations near the Rockgarden (Hill stratum 1 in Figure 1), and in Tolaga. Previous surveys had found relatively little orange roughy biomass in Tolaga, so this area at the time was abandoned in favour of Wairarapa, Clarence, and Kaikoura, where historical orange roughy biomass had been relatively high. Tolaga was revisited at the end of the survey, after a request to keep the Tolaga hill and surrounds clear of commercial gear was made via the Deepwater Group. The Tolaga strata were clear of commercial gear, and all but two Tolaga stations were successfully completed.

Sixteen stations were considered unsuitable for biomass estimation (Appendix 3). Most of these stations came fast (stations 10, 13, 51, 53, 60, 126, 147, and 148). Gear damage was suffered on stations 36, 62, 63, and 86, and included ripped wing and belly meshes or lost (imploded) floats or bobbins. The net damage on station 62 (in Tolaga) was extensive, and as a result the second net was used for all subsequent stations. Poor net statistics were recorded for stations 55, 85 and 184 (e.g., poor bottom contact or low headline height). On station 184 the poor net statistics were attributed to a large log stuck in the top of the net. Station 40 was rejected because the tow distance was too short.

On the second to last of the planned survey stations, on 10 April, *Tangaroa* caught roughly 50 t of alfonsino. The entire catch was successfully brought on board, but was too large to be processed. Therefore *Tangaroa* steamed to Napier to offload the fish to a commercial fish processor. As a result of this large catch there was insufficient time to complete the final remaining tow in stratum 17 (see Table 9).

Phase 2 tows for all strata except Tolaga were allocated on 3 April. Twenty-eight randomly allocated sites were investigated in stratum 23, of which 15 were successful. However, only 13 were in stratum 23 as two were mistakenly put into stratum 5 since the annotated charts used at sea were wrong. Three randomly allocated phase 2 sites were also completed in stratum 27, after completion of the Tolaga strata towards the end of the survey. The allocation of phase 2 tows to stratum 27 was determined from a revised phase 2 allocation (i.e., all phase 2 tows completed before Tolaga were excluded from a revised estimate of the phase 2 allocation). The net was flown above the seabed for four tows, with a median distance flown of 0.3 nautical miles.

Gonad samples were taken from 870 orange roughy and preserved in 10% buffered formalin, and stomachs were removed from 972 orange roughy and frozen (Table 11). Pairs of otoliths were removed from 2044 orange roughy (Table 11). A total of 1730 pairs of otoliths were removed from other species; predominantly basketwork eels, Johnson's cod, bigscale slickheads, smallscale slickheads, spiky oreo, smooth oreo, warty oreo, and white rattails. Dorsal spines were sampled from 60 leafscale gulper shark and 214 shovelnose dogfish.

During the voyage 275 species or species groups were recorded. These included 141 teleosts, including 35 macrouridae; 25 sharks, rays, and chimaeras; 16 octopus and squid; and 93 other invertebrates. A total of 14.31 km of fish were measured for length, consisting of 32 713 individual fish, measuring 10-167 cm in length (spiky oreo – frill shark), with an average length across all species of 50.0 cm. See Appendix 5 for a compilation of occurrence of fish species caught and biological measurements made. The green weight of the top 20 species is given in Table 10, with orange roughy accounting for 11.0% of the total catch from all trawls.

Invertebrate fauna represented 5 Porifera (sponges) 26 Cnidaria (anemones), corallimopharians (jewel anemones), corals (stony cup corals, black corals, sea fans, sea pens, soft corals, and jellyfish), 2 Mollusca (not cephalopods), 25 Crustacea (crabs and prawns), 1 polychaete (marine worm), 35 Echinodermata (sea stars and echinoderms), and a sipunculid (peanut worm). Other non-fish records included wood (taken on 58 tows), rocks, salps, rubbish, and discarded fishing gear (longlines).

#### 3.2 Orange roughy abundance estimate

Wingtip measurements were made on 36 tows, and ranged from 23.9 m to 26.4 m, with a mean of 25.4 m and standard deviation of 0.7 m. The depth range for the wingtip measurements was 800 to 1200 m. There was no discernable trend in wingtip distance with depth. There were 20 pairs of concurrent door spread and wingtip measurements, and the mean ratio of wingtip to door spread was 0.245. This ratio was 0.231 in 1992 (n=4), and 0.226 in 1994 (n=43). For this report, we have assumed a constant 25 m for the wingtip distance in 2010, i.e., estimating wingtip from door spread using the estimated ratio was not done.

The spatial distribution of orange roughy catches in 2010 was similar to that reported in 1993 and 1994 surveys, with highest catch rates on the Wairarapa coast (Figure 5). The *SurvCalc* parameter files used to estimate abundance for 2010 are in Appendix 6.

For the all-relevant-tows method, the total abundance of orange roughy was estimated to be 6800 t (c.v. 17%). This was lower than the average for the 1992–94 surveys of 15 300 t (c.v. 15%), with the main reduction in biomass occurring for juveniles (Table 12; Figure 6). A comparison of length frequencies by sub-areas for the four surveys shows that the main reduction in juveniles occurred in the three southern sub-areas (Kaikoura to Wairarapa) (Figure 7). Abundance estimates by stratum for all four surveys are in Appendix 7 (Table 7.1).

Using the first-at-site method and 10% allocation of phase 2 tows, the total abundance of orange roughy for 2010 was estimated to be 7100 t (c.v. 19%). This was lower than the average for the 1992–94 surveys of 16 200 t (c.v. 16%), with the main reduction in biomass occurring for juveniles (Table 13). Abundance estimates by stratum for all four surveys are in Appendix 7 (Table 7.2).

For both the all-relevant-tows and first-at-site methods, the adult orange roughy biomass in 2010 was not significantly different from that in 1992–94, but the biomass for juveniles was significantly lower in 2010 (at the 5% level) (Tables 12 & 13). Appendix 7 (Table 7.3) gives the abundance estimate by stratum for bycatch species.

#### 3.3 Comparability across surveys

The various trawl parameter estimates are shown for the 2010 and 1992–94 surveys in Tables 14 and 15. Door spread in 2010 was on average 6–7 m smaller, headline height in 2010 was about 1– 1.7 m lower, and trawling speed in 2010 was on average 0.2 knots lower than in 1993 and 0.4 knots lower that in 1994, but the same as in 1992 (Figure 8). The only high correlations between trawl parameters were between headline height and door spread (Figure 9), and between wingtip distance and door spread (not shown). There were insufficient environment data, and variability, to allow comparisons between trawl parameters and weather conditions.

The 2010 total catch abundances were similar and within the ranges for the 1992–94 surveys (Table 16), and therefore at this level, the net appeared to be working similarly in 2010 to the previous surveys. This assumes that the total biomass of all species has remained the same, even though some species may have declined or increased during the 16 year gap.

#### 3.4 Expected bias from using phase 2 stations

Table 17 shows the estimated bias from using different proportions of phase 2 tows. With more than a 10% allocation of phase 2 tows, the bias increased only slowly with greater allocation rate. There was little difference in the sample c.v.s for the different allocations of phase 2 tows.

The re-calculated abundances using the first-at-site method had phase 2 allocations of between 5% and 18% (Table 18). The re-calculated 2010 abundance assumed a 10% phase 2 allocation, therefore compared to the 1992–94 surveys no more than a 2% difference in phase 2 bias would be introduced. When using all relevant tows, the bias was about -10% for the 1993–94 surveys, and about -9% for the 2010 survey (Tables 17 & 19).

#### 3.5 Abundance estimates after excluding flown tows

As a sensitivity, all flown tows were excluded from all four surveys and the abundance reestimated using the all-relevant-tows method. The percentage change in total abundance from excluding flown tows varied between 1 and 5% (Table 20).

#### 4. DISCUSSION

The 2010 trawl survey was intended to provide a relative index of orange roughy biomass for use in quantitative stock assessment (Dunn 2005, 2009). The key requirement was therefore that the 2010 survey was as comparable as possible with the 1992–94 surveys. However, some differences in trawl parameters were observed between the 2010 and 1992–94 surveys, and the key questions are therefore (1) is this difference within the range of variability expected for the trawl, and (2) is the difference likely to substantially bias the time series with respect to the target species, orange roughy?

In 2010, the headline height was lower than in the 1992–94 surveys. The headline height expected for the orange roughy rough-bottom trawl net is 5–6 m (Grimes 1994), and therefore the headline height achieved in 2010 was either a little low, or within this range (see Figure 8). Conversely, the headline heights reported for the 1992–94 surveys tended to be a little higher than expected. The warp lengths used were similar in all surveys, so achieving a higher headline height in 2010 would have required more floats, or more layback, both of which would have exceeded the trawl net specifications (see Appendix 1).

The same orange roughy rough-bottom trawl was used by *Tangaroa* for surveys of spawning orange roughy on the north Chatham Rise in 1992 and 1994–96. These surveys reported a towing speed of 3.0–3.1 knots, a door spread of 114–121 m, and a headline height of 5.5–6.9 m (*Trawl* database, held at NIWA, Greta Point). The minimum door spread from the Chatham Rise surveys is actually greater than the median from the 1992–94 and 2010 MEC surveys, and the headline

height higher than the 2010 MEC survey, and similar to or lower than the 1992–94 MEC surveys. Combined with statistics from the MEC surveys themselves (see Table 14), the available trawl net parameters have a fairly wide range, and the 2010 surveys do not seem to be anomalous.

For comparison, trawl surveys on Chatham Rise and Campbell Plateau using *Tangaroa* and a full-wing hoki trawl have reported a headline height between 6.3 and 7.4 m, and a door spread between 114.2 and 126.5 m (Neil Bagley, pers. comm.). The expected variability for this trawl is therefore up to 1.1 m for headline height, and 12 m for doorspread. Trawl surveys on Challenger Plateau using FV *Thomas Harrison* used an orange roughy trawl similar to the MEC survey trawl, during 2005–06 and 2009–10, and reported a headline height between 5.3 and 5.9 m, and a door spread between 134 and 143 m (Doonan et al. 2010). The expected variability for this trawl is therefore up to 0.6 m for headline height, and 9 m for doorspread. The MEC surveys therefore show a relatively high variability in trawl parameters, which may reflect the wider range of ground over which this trawl was used (flat soft seabed through to rough ground, hills and seamounts).

In 2010, the wingtip distance was 1–4% higher, and the door spread was 5–7% lower, than reported for the 1992–94 surveys. This affects the area swept, which is of direct importance to the estimated abundance. However, the difference in swept area seems small relative to the c.v. of the abundance estimate, and to the magnitude of the decline in orange roughy abundance between 1992–94 and 2010, and is therefore not a major concern for the use of the results in stock assessment.

The achieved headline height is unlikely to be a concern for orange roughy catch rates, since orange roughy dive on approach of a trawl. Headline height would have an effect on catch rates if the orange roughy density was so high that the water column was saturated with fish, which may occur in spawning plumes, but such fish densities were not encountered during the MEC surveys. However, the higher headline may indicate that the net was fished "lighter" in the 1992–94 surveys, perhaps to reduce the risk of net damage or coming fast. All of the MEC surveys experienced some net damage. Fishing lighter might affect orange roughy escapement below and through the ground gear. Whilst the trawl has heavy ground gear, and so is expected to be in contact with the bottom, the higher headline height in the earlier surveys may allow the net to bounce more often. However, bouncing ground gear was recorded on the station forms only for a handful of tows (n<10; although small and short bounces may not be readily observed). Bouncing was not reported on the vast majority of the tows, therefore this affect should be minimal.

Other differences between trawl parameters for the MEC surveys were mean towing speed and the proportion of tows where the net was flown. Mean towing speed for 1994 was higher than the other surveys by 0.2–0.4 knots. The net was flown only for a small number of tows (4–5 tows for all surveys except 1992, where there were 12 such tows). Again, these differences are relatively minor and would not account for the decline in orange roughy abundance between 1992–94 and 2010.

The average distance between tows was larger in 2010 than 1992–94, because of the 2010 survey design, where only one tow from each site was occupied. The use of sites meant that some sites had repeat tows during the 1992–94 surveys (mainly affecting phase 2 tows), with the number of tows affected being about 40 per survey. This matters if there is spatial correlation of catch rates within a site, and catch rates were indeed found to be correlated within 4–5 km. However, the abundance estimates from the all-relevant-tows and first-at-site methods were found to be similar, although the c.v.s increased when using the first-at-site method.

There was little difference in the total abundance of bycatch across the four surveys. This result suggested that net efficiency was not dramatically different in any one survey. A regular increase or decrease in the bycatch abundance in a single survey might indicate a change in net performance, assuming that such a regular change would have been unlikely to have occurred naturally (or because of fishing). Even given constant net efficiency, we would expect some differences in catch rates because catchability will vary, perhaps because of environmental variation. Variable catchability is usually allowed for in stock assessment models by adding a 20% process error to trawl survey abundance indices.

In summary, the 2010 survey was different from the 1992–94 surveys in that the headline height was lower (~20%); the door spread was slightly smaller (~ 5%); the wingtip distance was slightly larger (~ 4%); the between tow distance was greater (especially for phase 2 tows); and the 1994 mean towing speed was slightly faster. The similarities between the surveys were that the same vessel, net, towing practice, survey design, and even some officers, were used; the warp-to-depth ratios were the same; the expected phase 2 bias was the same; the total bycatch abundances were similar; and the orange roughy vulnerability was similar (similar length range caught). Overall, there is little evidence that the trawl net was less efficient for orange roughy in 2010, and the differences in net parameters seem unlikely to explain the extent of the observed decrease in the biomass estimates for orange roughy.

#### 5. ACKNOWLEDGMENTS

Thanks to the scientific staff who participated in the voyage and officers and crew of RV *Tangaroa* for a safe and successful voyage. Thanks to Andy McKenzie for reviewing this draft. This work was carried out under Ministry of Fisheries project ORH2007/01.

2010	2.2	2	1.9	1.9	1.9	1.9	1.8	1.8	1.9	1.7

Table 16: The total abundance of bycatch species for the 1992–94 and 2010 surveys, with and without orange roughy included. The c.v. is derived from those for individual species abundances. Bycatch species used were: Basketwork eel, Baxters lantern dogfish, Bollons rattail, Catshark, *Centrophorus squamosus, Centroscymnus crepidater*, Deepsea cardinalfish, Four-rayed rattail, Hoki, Javelin fish, Johnson's cod, Long-nosed chimaera, Lucifer dogfish, *Nezumia namatahi*, Notable rattail, Pale ghost shark, Ribaldo, Ridge scaled rattail, Roughhead rattail, Serrulate rattail, Shovelnose spiny dogfish, Silver roughy, Slickhead bigscaled brown, Slickhead smallscaled brown, Small-headed cod, Smooth skin dogfish, Smooth oreo, Spiky oreo, *Trachyscorpia capensis*, Unicorn rattail, Warty oreo, White rattail, and Widenosed chimaera. Alfonsino was excluded, which had an abundance of 183 000 t in 2010.

Year	Total bycatch (`000 t)	C.v. (%)	Total with orange roughy (`000 (t)	C.v. (%)
1992	44	12	64	12
1993	52	9	66	8
1994	41	9	53	8
2010	51	11	58	10

Table 17: Expected bias and c.v. of abundance using varying amounts of phase 2 allocation of tows (5%, 10%, 15%, 20% and 25% of the number of phase 1 tows).

	Expected c.v.	
Phase 2 allocations (% of Phase 1 tows)	(%)	Expected bias (%)
5	15.0	-5.8
10	14.0	-7.8
15	13.8	-8.8
20	13.0	-9.3
25	13.0	-9.8

Table 18: The number of tows, number of phase 2 tows, and ratio of phase 2 to phase 1 tows, for the MEC trawl surveys, using the first-at-site method, and for 2010 using 10% allocation of phase 2 tows.

Year	Number of tows	Number of phase 2 tows	Ratio of phase 2 / phase 1 tows (%)
1992	137	13	10.5
1993	156	7	4.7
1994	160	24	17.6
2010	156	14	10

# Table 19: The number of tows, number of phase 2 tows, and ratio of phase 2 to phase 1 tows, for the MEC trawl surveys, using the all-relevant-tows method.

Year	Number of tows	Number of phase 2 tows	Ratio of phase 2 / phase 1 tows (%)
1992	171	36	27
1993	201	44	28
1994	201	43	27
2010	171	29	20

Table 20: The percentage change in total orange roughy abundance estimate after excluding flown tows.

Year	Abundance change
1992	+5%
1993	-1%
1994	-1%
2010	+1%

Figure 1: Survey area for the 1992–94 trawl surveys with the commercial ("Hill") strata used in 1993 & 1994 (Hill Stratum 1-3 were used in 1992). In 1993 & 1994, East Cape was a combined sub-area made up of East Cape in the north and Tolaga in the southern half of the sub-area shown in the plot. In 1992, there were two sub-areas, East Cape and Tolaga.

Figure 2: Tow positions showing clustering into sites. Examples plots are for strata 33 & 31. Red bars represents 2.25 nautical niles. Red circles on stratum 33 site 2 (top left) and stratum 31 site 3 (bottom right) are sites formed by merging 2 clusters by hand.

Figure 3: Survey sub-areas for the 2010 MEC trawl survey. Gray lines are the survey area and these are based on the 600 and 1500 m isobaths.

Figure 4: Location of valid biomass stations for the 2010 MEC orange roughy survey. Faded line is the 1000 m isobath.

Figure 5: Total orange roughy catch rate (kg.km<sup>-1</sup>) for valid biomass stations and the 2010 MEC trawl survey, plotted by tow start position. Circle area is proportional to catch rate; maximum 487 kg.km<sup>-1</sup>, +, zero catch of orange roughy. Faded line is the 1000 m isobath.

Figure 6: Estimated orange roughy numbers-at-length for the four MEC trawl surveys, 1992–94 and 2010, using the all-relevant-tows method.

Figure 7: Orange roughy length frequency distributions for the four MEC trawl surveys by sub-area. Frequencies were constructed assuming a 1:1 sex ratio.

Figure 7 (cont.): Orange roughy length frequency distributions for the four MEC trawl surveys by sub-area. Frequencies were constructed assuming a 1:1 sex ratio.

Figure 8: MEC trawl survey trawl parameter distributions. Door distances were trimmed at 150 m. Del = start – finish depth.

Figure 9: Headline height versus door spread for the MEC trawl surveys. Points labelled 2, 1992; 3, 1993; 4, 1994; 0, 2010. Lines show lowess smoothers through the data; dark solid line, 1992; dotted line, 1994; lower solid line, 2010.

The *RV Tangaroa* trawl doors:

- Size 6.1 square meters
- Manufactured by Kernohan Engineering Nelson
- Weight 2.3 t in air
- Last major overhaul around 2005

#### Warps:

- 28 mm, 6x19 construction, steel core galvanised wire rope.
- Brand ex Cookes (manufactured in Auckland)
- Diameter 28 mm
- Top 2000 m about 3 years old, bottom 2000 m about 18 months old
- Left hand and right hand lay.

#### Winches:

- Main trawl winches are Hydraulic Brattvagg self tensioning
- Control unit Hydraulic Brattvagg 1991 to ~June 2008. Scantrol ~June 2008 to present
- Date of last major winch overhaul 2002.
- Date of last control system check 23 November 2009
- Winch settings available on request (contact N. Bagley, NIWA)

#### Sweeps:

- 6 x19 galvanised wire rope
- Diameter 28 mm
- Length 50 m
- RH lay

#### Bottom Bridle:

- 6 x19 galvanised wire rope
- Diameter 28 mm
- Length 50 m
- RH lay

#### Top Bridle:

- 6 x19 galvanised wire rope
- Diameter 24 mm
- Length 50 m
- RH lay

Net Electronics:

- Net monitor: Original Kajo Denki KCN 300 replaced with CN22 in mid 1990's. New CN22 net monitor headline unit (January 2010).
- SCANMAR doorspread and wingspread sensors. Various ages i.e. replaced as required.

#### Appendix 2: Sites and their associated tows

Table 2.1: Sites and their associated tows. Site code is ssll, where ss is the stratum number and ll is a letter code, A, B, ..., e.g., "11B" is in stratum 11 and it is the B(second) site. Tow code is yy-ss, where yy is year and ss is station number in that year, e.g., "93-178" is station 178 in the 1993 survey. There are 115 sites that are common to all years (and by design to 2010, but in practice there were 114 since one common Phase 1 tows could not be done).

# Appendix 4: Timetable

18 March	Mobilisation of <i>Tangaroa</i> . Departed Wellington at 1930 hrs on 18 March.
19 March	First shot on Wairarapa coast abandoned due to an earlier than anticipated start of the seismic survey by <i>MV Reflect Resolution</i> . In order to avoid possible effects that the seismic survey might have on fish catachability, <i>Tangaroa</i> relocated roughly 110 km north, and then worked north completing survey stations in north Wairarapa and south Portland.
20 March	Worked north, completed survey stations in Madden, and south Portland.
21–24 March	Worked from shallow to deep across the Madden and Portland strata, including the stations in the Rockgarden hill strata.
25–26 March	Completed tows in Ritchie and worked north into Tolaga. Repeated net damage was suffered on the Tolaga stations, with net 1 damaged beyond immediate repair on the second Tolaga station. Substantial net damage and repair occurred on two further stations. Five commercial fishing vessels had set longlines across the Tolaga hill and surrounding area, preventing access to eight stations.
27 March	The longline gear was not clear of the Tolaga stations, and as a result <i>Tangaroa</i> left the Tolaga stratum for Wairarapa, completing remaining stations in the Ritchie and Madden strata on the way. Access to a station near the Rockgarden hills was not possible because of commercial longlines.
28-30 March	Completed stations in Wairarapa.
31 March – 1 April	Completed stations in Clarence.
2 April – 3 April	Completed stations in Kaikoura. The Phase 1 stations were completed late on the 3 <sup>rd</sup> April.
4 April	Completed Phase 2 stations in Kaikoura, and then steamed overnight to Wairarapa.
5 April – 8 April	Completed Phase 2 stations in Wairarapa.
8 April	Steamed north to Tolaga, repeating two tows in the Portland stratum on the way; these were tows that were unsuccessful during phase 1 of the survey. The Tolaga area was found to be free of commercial fishing gear.
9 – 10 April	Completed stations in Tolaga outstanding from phase 1, and 3 phase 2 stations. The second to last planned tow caught roughly 40 t of alfonsino, and because this could not be processed at sea, <i>Tangaroa</i> steamed to Napier to offload the fish.
11 April	Tangaroa left Napier for Wellington at 0830.
12 April	Tangaroa arrived in Wellington, berthing at 0800 hrs.

#### Appendix 5: Occurrence and biological measurements for fish species caught

Table 5.1: MEC trawl survey 2010 number of stations where each fish species was caught (Occurrence), the number of tows where each species was sampled, and the number of fish measured for length, weight, sex, and macroscopic maturity stage. Weight, sex, and macroscopic maturity stage samples are a subset of the length samples. Data for all valid stations.; where the tow was invalid orange roughy were sampled for biological statistics, but all other species were measured for catch weight only. Only statistics for species caught in five or more valid stations are shown.

Table 7.3: For species other than orange roughy, abundances (Abd, t) and c.v. (%) from the 1992–94 and 2010 surveys using all relevant tows. Also shown is the mean abundance over the 1992–94 surveys, the ratio of the change between the mean 1992–94 abundance to that from 2010, and the t-test of the mean 1992–94 abundance to 2010 (coded yellow for significant at the 5% level).
