

1. FISHERY SUMMARY

1.1 Commercial fisheries

Red cod are targeted primarily by domestic trawlers in the depth range between 30 and 200 m and are also a bycatch of deepwater fisheries off the southeast and southwest coasts of the South Island. The domestic red cod fishery is seasonal, usually beginning in November and continuing to May or June, with peak catches around January and May. During spring and summer, red cod are caught inshore before the fishery moves into deeper water during winter. Red cod entered the QMS in 1986.

Reported annual catches by nation from 1970 to 1986–87 are given in Table 1. Foreign vessel catches declined during the 1980s and were negligible by 1987–88.

Reported landings for 1931 to 1982 are given by red cod QMAs 1, 2, 3, and 7 in Table 2. Recent reported landings and TACCs of red cod by Fishstock are shown in Table 3, and Figure 1 depicts historical landings and TACC values for the three main RCO stocks.

Table 2: Reported landings (t) for the main QMAs from 1931 to 1982.

The 1931–1943 years are April–March but from 1944 onwards are calendar years.
 Data up to 1985 are from fishing returns; data from 1986 to 1990 are from Quota Management Reports.
 Data for the period 1931 to 1982 are based on reported landings by harbour and are likely to be underestimated as a result of underreporting and discarding practices. Data include both foreign and domestic landings. Data were aggregated to FMA using methods and assumptions described by Francis & Paul (2013).

¹Commercial catch allowance increased through application of in-season MP with additional ACE provided under S68 of Fisheries Act 1996.

²Recommended commercial catch allowance increase to 6289 t consulted but not implemented.

*FSU data.

§ Includes landings from unknown areas before 1986-87.

The bulk of reported landings are taken from RCO 3, in particular the Canterbury Bight and Banks Peninsula areas. The red cod fishery is characterised by large variations in catches between years. Research indicates that this interannual variation in catch is due to varied recruitment causing biomass fluctuations rather than a change in catchability. The RCO 3 TACC was reduced by 63% from 1 October 2007 to 4600 t, with the TAC being set at 4930 t (customary, recreational, and other sources of mortality were allocated 5 t, 95 t, and 230 t, respectively). All RCO stocks fisheries have been put on to Schedule 2 of the Fisheries Act 1996. Schedule 2 allows that for certain 'highly variable' stocks, the Total Annual Catch (TAC) can be increased within a fishing season. Increased commercial catch is provided for through the creation of additional 'in-season' ACE. The base TACC is not changed by this process and the 'in-season' TAC reverts to the original level at the end of each season. The RCO 2 TAC was increased under Schedule 2 in 2012–13 and 2016–17 and the RCO 3

TAC was increased in 2012–13 and 2013–14 (see Table 3). The 2016–17 RCO 2 increase was not authorised until late August, too late for the fishery to respond. A recommended RCO 3 commercial catch allowance increase to 6289 t in 2014–15 was not implemented because discussions with commercial operators concluded that the increase was not required for that fishing year and that management resources would be better allocated elswhere. RCO 3 landings were below 2000 t in 2018–19, 2019–20, and 2020–21.

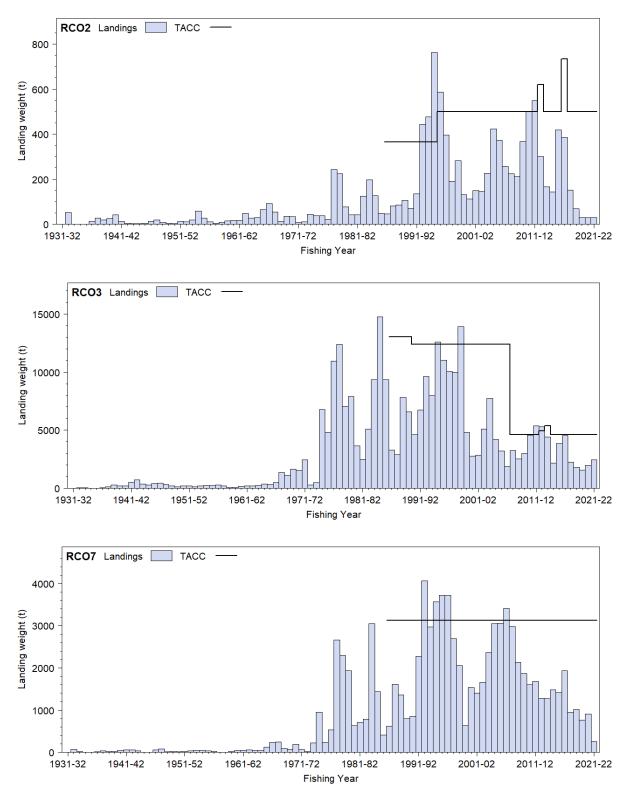

Figure 1: Reported commercial landings and TACC for the three main RCO stocks. Top to bottom: RCO 2 (Central East), RCO 3 (South East Coast), and RCO 7 (Challenger). RCO 2 and RCO 3 show in-season adjustments to the commercial limit.

1.2 Recreational fisheries

Recreational fishers take red cod throughout New Zealand. Estimates of harvest from telephone/diary surveys conducted between 1991 and 2000 are given in Table 4a.

Table 4a: Estimated number and weight of red cod harvested by recreational fishers, by Fishstock and survey. Surveys were carried out in different years in the MAF Fisheries regions: South in 1991–92, Central in 1992–93, North in 1993–94 (Teirney et al 1997) and nationally in 1996 (Bradford 1998) and 1999–00 (Boyd & Reilly 2004). Survey harvest is presented as a range to reflect the uncertainty in the estimates.

| Fishstock | Survey | Number | CV % | Estimated harvest range (t) | Estimated point estimate (t) 1991–92 |

| RCO 1 | National | 21 000 | 36 | 5-11 | 8 |
| RCO 2 | National | 39 000 | 25 | 8-14 | 11 |
| RCO 3 | National | 207 000 | 25 | 210-349 | 280 |
| RCO 7 | National | 23 000 | 50 | 5-14 | 9 |

The harvest estimates provided by these telephone/diary surveys are no longer considered reliable for various reasons. A Recreational Technical Working Group concluded that these harvest estimates should be used only with the following qualifications: a) they may be very inaccurate; b) the 1996 and earlier surveys contain a methodological error; and c) the 2000 and 2001 estimates are implausibly high for many important fisheries. In response to these problems and the cost and scale challenges associated with onsite methods, a national panel survey was conducted for the first time throughout the 2011–12 fishing year. The panel survey used face-to-face interviews of a random sample of 30 390 New Zealand households to recruit a panel of fishers and non-fishers for a full year (Wynne-Jones et al 2014). The panel members were contacted regularly about their fishing activities and harvest information in standardised phone interviews. The national panel survey was repeated during the 2017–18 fishing year using very similar methods to produce directly comparable results (Wynne-Jones et al 2019). Recreational catch estimates from the two national panel surveys are given in Table 4b. Note that national panel survey estimates do not include recreational harvest taken under s111 general approvals.

 Table 4b: Recreational harvest estimates for red cod stocks (Wynne-Jones et al 2014, 2019). Mean fish weights were obtained from boat ramp surveys (Hartill & Davey 2015, Davey et al 2019).

| Stock | Year | Method | Number of fish | Total weight (t) | CV |
|-------|---------|--------------|----------------|------------------|------|
| RCO 1 | 2011-12 | Panel survey | 2 949 | 3.1 | 0.32 |
| | 2017-18 | Panel survey | 2 300 | 2.4 | 0.34 |
| RCO 2 | 2011-12 | Panel survey | 20 637 | 24.7 | 0.18 |

1.3 Customary non-commercial fisheries

Quantitative estimates of the current level of customary non-commercial catch are not available.

1.4 Illegal catch

Quantitative estimates of the level of illegal catch are not available.

1.5 Other sources of mortality

Processing limits on red cod are sometimes imposed to discourage fishers from landing red cod when the species cannot be processed or when markets are poor. This practice has encouraged dumping. Processing limits are currently less of a problem than in earlier years.

2. BIOLOGY

Red cod are a fast-growing, short-lived species with few fish in the commercial fishery older than six years. Red cod grow to about 25 cm total length (TL) in the first year, followed by annual growth increments of around 15, 10, and 5 cm. Growth of sexes is similar for the first two years, after which females tend to grow faster than males and reach a larger overall length. Sexual maturity ranges from 45 to 55 cm TL with a mean value of 52 cm TL for both sexes at an age of 2–3 years. *M* has been estimated to equal 0.76 for both sexes. In 1995, ageing of red cod was validated using marginal zone analysis.

In the 1989–90 to 1992–93 fishing years, 80% of the landings in RCO 3 were 2+ and 3+ fish (50– 57 cm TL). The sex ratio of the commercial catch during this period was skewed towards females during November (F:M ratio of 3.4:1) with the ratio tending to even out by May. Schools generally comprise single age cohorts rather than a mix of age classes.

Spawning in red cod varies with latitude, with spawning occurring later at higher latitudes. In the Canterbury Bight, spawning occurs from August to October. No definite spawning grounds have been identified off the southeast coast, but there is some evidence that red cod spawn in deeper water (300–750 m). Running ripe fish were caught on the Puysegur Bank in 600 m during the Southland trawl survey in February 1994. Juvenile red cod are found in offshore waters after the spawning period; however, no nursery grounds are known for this species.

Red cod are seasonally abundant, with schools appearing in the Canterbury Bight and Banks Peninsula area around November. These schools are feeding aggregations and are not found in these waters after about June. Catch data indicate that they move into deeper water after this time. Recruitment is highly variable resulting in large variations in catches between years.

Biological parameters relevant to the stock assessment are shown in Table 5.

Table 5: Estimates of biological parameters for red cod.

3. STOCKS AND AREAS

The number of red cod stocks is unknown. There is no information about stock structure, recruitment patterns, or other biological characteristics that would indicate stock boundaries.

4. STOCK ASSESSMENT

No recent stock assessments have been carried out on any red cod stocks. Previous assessments were undertaken; however, these are now outdated. Details appear in previous versions of the Plenary report.

Trawl survey biomass estimates are available from four Southland *Tangaroa* surveys, five summer and twelve winter east coast South Island (ECSI) *Kaharoa* surveys, and fourteen west coast South Island (WCSI) autumn *Kaharoa* surveys (Table 6, Figures 2 and 3).

4.1 Biomass estimates

East coast South Island inshore trawl survey

The ECSI winter surveys from 1991 to 1996 in 30–400 m were replaced by summer trawl surveys (1996–97 to 2000–01) which also included the 10–30 m depth range; but in 2001, the Inshore WG recommended that the summer ECSI trawl survey be discontinued because of the extreme fluctuations in catchability between surveys (Francis et al 2001). The winter surveys were reinstated in 2007 and this time included additional 10–30 m strata in an attempt to index elephantfish and red gurnard which were officially included in the list of target species in 2012. The 2007 survey and all surveys from 2012 onwards provide full coverage of the 10–30 m depth range. The winter surveys are currently conducted on a biennial cycle.

Following the resumption of the winter surveys in 2007, red cod core strata biomass was low relative to the period in the 1990s, except for large estimates in the 2012 and 2021 surveys, which were a result of a few large catches associated with inflated CVs (Figure 2, Table 6) (Beentjes et al in press). The biomass in 2021 increased by 10-fold and was the highest in the time series following the lowest in 2018, although the associated CVs were very high for both of these surveys (2018 = 83%; 2021 = 69%). The 2022 biomass was of similar magnitude to the surveys from 2007 onward, excluding the two extreme values in 2012 and 2021 (Table 6, Figure 2) (Beentjes et al in press). The relatively high biomass in 1994 and the low biomass in 2007–09 are consistent with commercial landings in RCO 3, a fishery in which cyclical fluctuating catches are characteristic. The large biomass in 2012 consisted predominantly of 1+ year fish. The proportion of pre-recruit biomass in the core strata varied greatly among surveys ranging from 6% to 59% of the total biomass and in 2022 it was 11%. The proportion of juvenile biomass (based on the length-at-50% maturity) also varied greatly among surveys, with corresponding peaks in 1994 and 2012 of about 70% juvenile; in 2022, juvenile biomass was relatively low at 11%.

The additional red cod biomass captured in the 10–30 m depth range accounted for 5% or less of the biomass in five of the seven core plus shallow strata (10–400 m) surveys. However, in 2014 and 2022, it accounted for substantially more (44% and 34%, respectively) of the total biomass—indicative of the sporadic importance of shallow strata for red cod and the variable nature of red cod catches (Table 6, Figure 2) (Beentjes et al in press). The addition of the 10–30 m depth range had little effect on the shape of the length frequency distributions in any of the six surveys, except 2014 when the largest fish (over 60 cm) were in 10–30 m.

The spatial distribution of red cod aggregations (large catches) varied geographically among surveys and was in contrast to more frequent zero or very small catches. Overall, however, this species was consistently well represented over the entire survey area, most commonly from 30 m to about 300 m.

West coast South Island inshore trawl survey

Total biomass estimates were high and fairly stable for the first four surveys (early 1990s), varying from 2546 t to 3169 t. There was a sharp decline in 2000 to 414 t, but the biomass gradually increased to pre-decline levels by 2009. The 2021 survey biomass estimate of 768 t was the third lowest in the time series (MacGibbon et al 2022), up from 666 tonnes in 2019 (the second lowest estimate in the time series), and was part of an overall declining trend since 2009 (Table 6, Figure 3).

Although total red cod biomass increased in 2021, adult biomass decreased, particularly adult males (MacGibbon et al 2022). Adult (over 50 cm TL) biomass was 122 t, about 16% of the total, down from about 36% of the total biomass in 2019. Most of the increase in 2021 was of juveniles. Only a small proportion of red cod caught on the survey are from Tasman Bay and Golden Bay, with most coming from the west coast in depths less than 200 m.

Table 6: Relative biomass indices (t) and coefficients of variation (CV) for red cod for east coast South Island (ECSI) - summer and winter, west coast South Island (WCSI), and Southland survey areas*. Biomass estimates for ECSI in 1991 have been adjusted to allow for non-sampled strata (7 & 9 equivalent to current strata 13, 16, and 17). The sum of pre-recruit and recruited biomass values do not always match the total biomass for the earlier surveys because at several stations length frequencies were not measured, affecting the biomass calculations for length intervals. – , not measured; NA, not applicable. Recruited is defined as the size-at-recruitment to the fishery (40 cm).

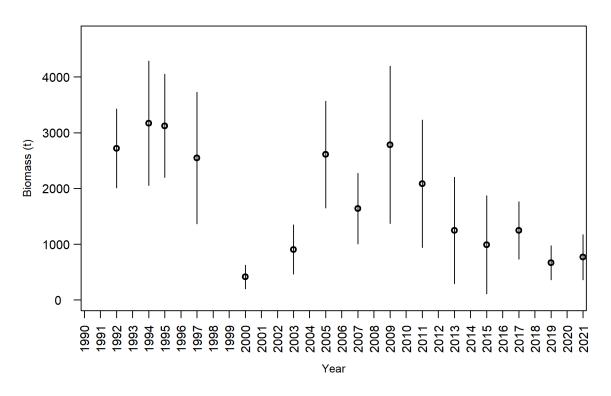

Figure 3: Biomass estimates from the west coast South Island inshore trawl survey. Error bars are ± two standard deviations.

4.2 Length frequency distributions

East coast South Island inshore trawl survey

The size distributions of red cod in each of the fourteen core strata (30-400 m) ECSI surveys were similar and generally characterised by a 0+ mode (10-20 cm), 1+ mode (30-40 cm), and a less defined right-

hand tail comprised predominantly of 2+ and 3+ fish (Beentjes et al in press). The 1996 to 2009 surveys showed poor recruitment of 1+ fish compared with earlier surveys, followed by the strongest 1+ cohort of all surveys in 2012, and then by weak recruitment in 2014 to 2018. In 2021, the 1+ cohort was the strongest since 2012 but less distinct, merging into the older cohorts. In the 2022 survey, all cohorts were relatively weak. Red cod off the ECSI, sampled during these surveys, were generally smaller than those from Southland, suggesting that this area may be an important nursery ground for juvenile red cod. The addition of the 10–30 m depth range had little effect on the shape of the length frequency distributions except in 2014, when the largest female fish (over 60 cm) were in less than 30 m (Beentjes et al in press).

West coast South Island inshore trawl survey

The size distributions of red cod from the WCSI surveys are similar to that seen in the ECSI with a 0+ mode (10–20 cm), 1+ mode (25–40 cm), and a less defined right-hand tail that comprised predominantly 2+ and 3+ fish. The length frequency had no obvious modes in 2021, unlike most other years, where 0+, 1+, and occasionally 2+ fish were discernible. Strong cohorts of 1+ fish (approximately 24– 35 cm) have been visible in a number of years, particularly in all surveys from 2005 to 2013 but have not been seen since. Assuming that fish under 23 cm are a 0+ cohort, a mode of 0+ fish under 23 cm may be present in the 2021 data, but the right shoulder of the mode blends into the rest of the length frequency distribution. The presumed 0+ 2021 cohort is the largest seen, but most fish are between 18 and 23 cm and smaller fish are lacking, unlike previous years.

RCO 2 and RCO 3 in-season management procedure

Management procedures (MP), used to inform in-season adjustments to the RCO 2 and RCO 3 commercial catch, were developed in 2013 by Bentley & Langley (2013). These MPs were based on a predictive relationship between annual standardised CPUE for RCO 2 (or RCO 3) with the total annual RCO 2 (or RCO 3) landings which effectively estimate an average exploitation rate in either QMA (Figures 4 and 5, left panels). A standardisation model is used to predict the annual CPUE for the active fishing year based on the accumulated data to the month preceding the evaluation month. The parameters from the predictive regression are then applied to the index based on incomplete data from the final year in the standardised model, resulting in a prediction of the full-season commercial catch. The partial year in-season estimate of standardised CPUE is used as a proxy for the final annual index, with the recommended catch defined by the slope of the regression line (Figures 4 and 5) multiplied by the CPUE proxy estimate. The 2013 MP rule stipulated that:

- a) only years which were less than 90% of the full-season commercial catch allowance were used in developing the Figure 4 and Figure 5 regressions;
- b) the regression would be forced to go through the origin (i.e., estimated without a constant);
- c) only the positive catch data would be used in developing the standardised index.

Review of the RCO 2 and RCO 3 MPs

The RCO 2 and RCO 3 MPs were reviewed on a five-year cycle in 2018 (Starr & Kendrick 2019a). The basic structure of each MP was retained, with the predictive model based on the regression of total annual CPUE with the landings in the corresponding year. Total annual CPUE for the fishing year in progress was estimated from the partial year data accumulated to the end of a specified month. However, the components of the MP were individually evaluated with following changes made:

- a) all years were included in the predictive regression (Figures 4 and 5), because no bias was detected among the residuals, even those where the catch exceeded 90% of the full-season commercial catch allowance;
- b) the regression was estimated with a constant (Figures 4 and 5). This made little difference for the RCO 3 predictive regression (because the constant in that regression is not statistically significant) but the residuals in the RCO 2 regression were badly skewed when the regression was forced through the origin;
- c) a binomial presence/absence standardised model was also fitted and then combined with the positive catch standardised model. This was done because the SINSWG has determined that such models are more likely to capture all components of the CPUE trends.

Figures 6 and 7 show the respective operation of the RCO 2 and RCO 3 MPs up to 2017–18 and predicting the 2018–19 fishing year. These rules have moderate predictive capability as was demonstrated by a retrospective analysis which showed that the absolute relative error for CPUE (=100*abs(prediction-annual)/annual) in the predictions averaged from 32% (December) to 16% (April) (months indicate the final month in the predictive year) for RCO 2 and 24% (December) to 13% (April) for RCO 3. The WG recommended that data be accumulated up to the end of January, if possible, because the drop in absolute relative error between those two months was sufficient to justify the delay (from 32% to 28% for RCO 2 and from 24% to 20% for RCO 3).

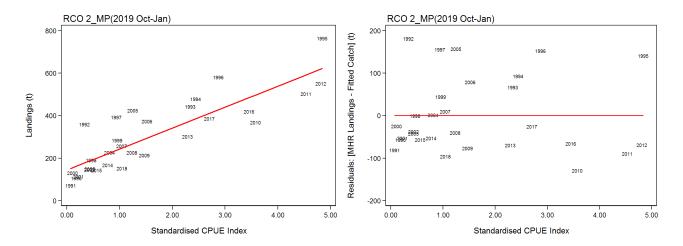

Figure 4: Relationship between annual RCO 2 CPUE and total annual RCO 2 QMR/MHR landings from 1989–90 to 2017–18; [left panel]: regression based on TACC and declared landings for all years; [right panel]: residuals from the left panel regression.

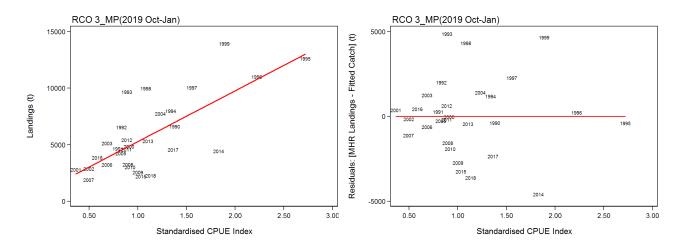

Figure 5: Relationship between annual RCO 3 CPUE and total annual RCO 3 QMR/MHR landings from 1989–90 to 2017–18; [left panel]: regression based on TACC and declared landings for all years; [right panel]: residuals from the left panel regression.

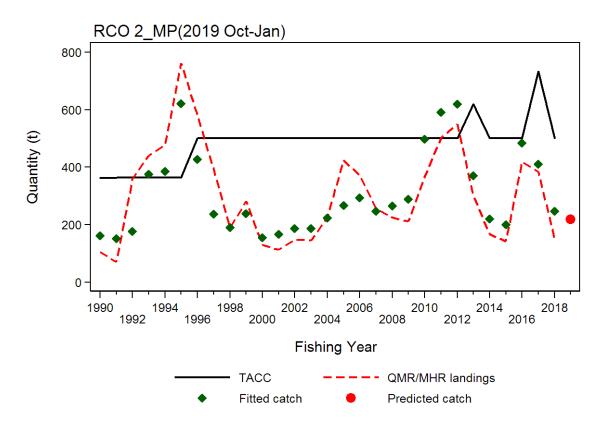

Figure 6: Operation of the 2019 MP for RCO 2, showing the relationship of the fitted catch estimates to the observed MHR/QMR landings and the annual recommended catches for all years to 2017–18 based on the estimated standardised CPUE up to the end of January. The TACC line includes approved additional ACE for the year, if present.

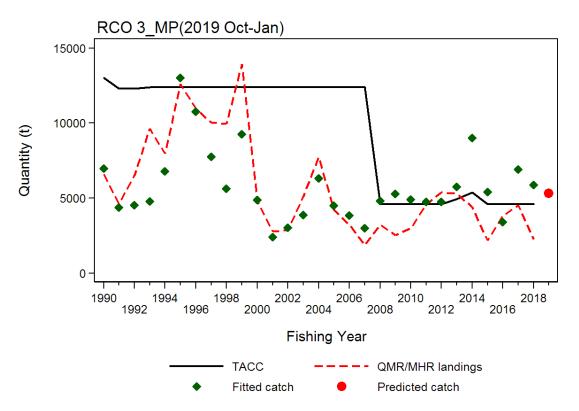

Figure 7: Operation of the 2019 MP for RCO 3, showing the relationship of the fitted catch estimates to the observed MHR/QMR landings and the annual recommended catches for all years to 2017–18 based on the estimated standardised CPUE up to the end of January. The TACC line includes approved additional ACE for the year, if present.

Operation of the RCO 2 and RCO 3 MPs

The 2013 MP for RCO 2 was operated six times from 2013 up to and including 2018 (Table 7). Even though the RCO 2 MP was reviewed in 2018, the operation of the MP preceded the review and thus used the earlier procedure. Only two of the six evaluations resulted in a recommendation for a commercial catch allowance increase in RCO 2 (Table 7), with the other years coming in near to or less than the current TACC of 500 t. The operation of the revised RCO 2 MP in 2019, using data accumulated up to the end of January, resulted in no increase in the commercial catch allowance (Table 7).

The 2013 MP for RCO 3 was operated six times from 2013 up to and including 2018 (Table 7). Even though the RCO 3 MP was reviewed in 2018, the operation of the MP preceded the review and thus used the earlier procedure. Four of the six evaluations resulted in a recommendation for a commercial catch allowance increase (Table 7), with the other two years coming in at less than the current TACC of 4600 t. The operation of the revised RCO 3 MP in 2019, using data accumulated up to the end of January, resulted in a recommendation for an increase of 712 t in the commercial catch allowance (which was declined by Industry) (Table 7).

Establishing B_{MSY} compatible reference points for RCO 2 and RCO 3

Given the large recruitment-driven fluctuations in biomass observed for RCO, a target biomass is not meaningful. In-season adjustments are therefore based on relative fishing mortality, with increases made when this drops below the target value. F_{MSY} proxies accepted for RCO 2 and RCO 3 are the relative fishing mortality values calculated by dividing the baseline TACCs by the corresponding CPUE values on the landings: CPUE regressions shown in Figures 4 and 5, respectively.

| Prediction year | Fishing year | CPUE prediction | CPUE total year ¹ | Recommended commercial allowance | Approved commercial allowance ² | Full- season catch (t) | Date of approval ² | Reference |

* MP operation that resulted in a commercial catch allowance increase recommendation.

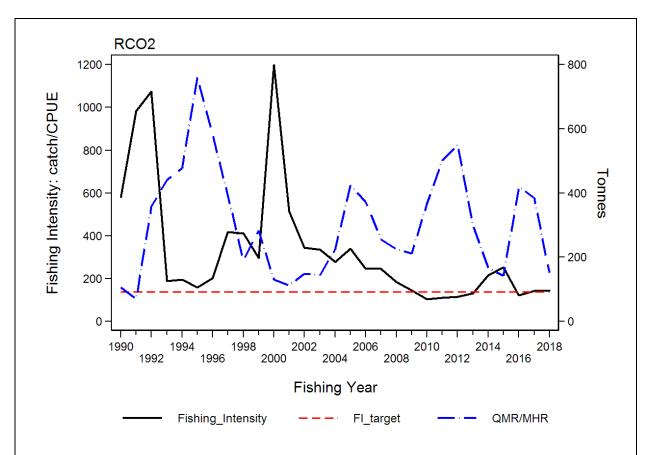

5. STATUS OF THE STOCKS

Yearly fluctuations in red cod catch reflect changes in recruitment. Trawl surveys and catch sampling of red cod have shown that the fishery is based almost exclusively on two and three year old fish and is highly dependent on recruitment success. RCO 2 and 3 are presently managed using in-season adjustments based on a decision rule and associated management procedure.

• RCO 2

| Stock Status | |
|-----------------------------------|--|
| Year of Most Recent Assessment | 2018 |
| Assessment Runs Presented | Standardised CPUE and relative exploitation rate |
| Reference Points | Target: F_{MSY} proxy |

Fishery Interactions

Red cod are primarily taken in conjunction with the following QMS species: stargazer, red gurnard, tarakihi, and various other species in the west coast South Island target bottom trawl fishery. Smooth skates are caught as a bycatch in this fishery, and the biomass index for smooth skates in the west coast trawl survey has declined substantially since 1997. There may be similar concerns for rough skates but the evidence is less conclusive. Incidental captures of seabirds occur.
